## Sensor Networks -- > Internet of Things

Wireless Sensor Networks (WSN), <https://www.linkedin.com/pulse/internet-things-part-7-wireless-sensor-networks-mahendra-bhatia>

“WSN technology applications for smart grid, smart water, intelligent transportation systems, and smart home generate huge amounts of data, ...

The term internet of things refers to uniquely identifiable objects and their virtual representations in an “internet-like” structure. These objects can be anything from large buildings, industrial plants, planes, cars, machines, any kind of goods.” \*

---

\*An article by Mahendra Bhatia at <https://www.linkedin.com/pulse/internet-things-part-7-wireless-sensor-networks-mahendra-bhatia>

## Challenges: Requirements and System Characteristics

- Variety of operations/applications:
  - Detection, Identification, Estimation, Learning
  - Signal Processing, Communication
  - Data Processing: Storage and Retrieval, Data Association, Data Mining, Clustering
  - Resource Allocation, Optimization and Control
  
- A wide range of performance requirements
  - Reliability, Robustness, Sustainability
  - Efficiency, Fairness
  - Security, Privacy
  
- Characteristics of the problems arising in the networked systems
  - Mobility, variability with time (not necessarily predictable)
  - Size (number of nodes/agents or number of the decision and/or constraints)

## Agreement Problem

- Consider a connected network of  $m$ -agent, each knowing its own scalar value  $x_i(0)$  at time  $t = 0$ .
- The problem is to design a distributed and local algorithm ensuring that **the agents agree on the same value  $x$** , i.e.,

$$\lim_{t \rightarrow \infty} x_i(t) = x \quad \text{for all } i.$$

### Algorithm for Static Network Topology

each agent performs the following updates

$$x_i(t + 1) = \sum_{j \in N_i} a_{ij} x_j(t) \quad \text{for all } i$$

where  $N_i$  is the set of neighbors of agent  $i$  in the network (including itself), and  $a_{ij} > 0$  with  $\sum_{j \in N_i} a_{ij} = 1$ .

## Agreement and Optimization

- Suppose now each agent  $i$  has a local objective  $f_i(x)$
- The agents are connected through an undirected graph  $\mathbb{G}$  and can communicate locally
- Each agent can perform computations and has a buffer
- They need to cooperatively solve the following network problem

$$\text{minimize } \sum_{i=1}^m f_i(x) \quad \text{subject to } x \in \mathbb{R}^n$$

where each  $f_i$  is locally known to agent  $i$  only

- We assume that each  $f_i$  is convex and differentiable<sup>†</sup>

---

<sup>†</sup>For sake of discussion, convex and nondifferentiable will also work

- Assuming (for the moment) that the graph is static, connected and undirected
- Distributed and local consensus-based algorithm<sup>‡</sup>

$$x_i(t + 1) = \left( \sum_{j=1}^m a_{ij} x_j(t) \right) - \alpha_t \nabla f_i(x_i(t))$$

or

$$x_i(t + 1) = \left( \sum_{j=1}^m a_{ij} x_j(t) \right) - \alpha_t \nabla f_i \left( \sum_{j=1}^m a_{ij} x_j(t) \right)$$

where  $a_{ij} > 0$  if  $j \in N_i \cup \{i\}$  and  $a_{ij} = 0$  otherwise, and  $\alpha_t > 0$  is a stepsize

**Basic Convergence Result:** assuming that the problem has a solution, the graph  $\mathbb{G}$  is connected, the matrix  $A$  is doubly stochastic, the gradients are bounded and stepsize satisfies  $\sum_{t=0}^{\infty} \alpha_t = +\infty$  and  $\sum_{t=0}^{\infty} \alpha_t^2 < \infty$ , one can show that

$$\lim_{t \rightarrow \infty} x_i(t) = x^* \quad \text{for all } i$$

for an optimal solution  $x^*$ .

- In terms of time convergence the rate is of the order of  $O(\frac{\ln t}{\sqrt{t}})$ .
- If the function  $\sum_{i=1}^m f_i(x)$  is strongly convex the rate is of the order of  $O(\frac{\ln t}{t})$

---

## Algorithm Properties

- It is robust to network delays and other imperfections (e.g., missed messages)
- It can solve online problems, where the functions  $f_i$  may change with time
- It is efficient when dealing with (possibly stochastic) computational and/or communication errors
- Reliable and efficient in imperfect situations
- Extendable to variants for solving saddle-point problems and games

## Drawback: Balanced-Graph Requirement

$$x_i(t + 1) = \left( \sum_{j=1}^n a_{ij} x_j(t) \right) - \alpha_t \nabla f_i(x_i(t))$$

- The matrix  $A$  **has to be doubly stochastic**, otherwise if only row-stochastic the algorithm would produce the iterates converging to a point that solves the problem

$$\text{minimize } \sum_{i=1}^m \pi_i f_i(x),$$

where  $\pi' A = \pi'$ .

**The algorithm cannot be efficiently implemented in directed time-varying graphs<sup>§</sup>**

- An alternative to the weighted averaging is available through *push-sum algorithm* for consensus\*<sup>¶</sup>

## Push-sum: Column Stochastic Matrix

- Given a directed and strongly connected graph  $([m], E)$ , let  $A$  be a matrix compatible with the graph

$$A_{ij} = 0 \quad \text{when } (j, i) \notin E$$

- Assume that  $A$  has positive diagonal entries
- Also, let  $A$  be a column-stochastic matrix

$$A_{ij} \geq 0 \quad \text{for all } i, j \quad \text{and} \quad \mathbf{1}'A = \mathbf{1}'$$

where "prime" denotes the transpose and  $\mathbf{1} = [1; \dots; 1]$

- Then

$$\lim_{t \rightarrow \infty} A^t = \pi \mathbf{1}'$$

where  $\pi$  is a stochastic vector with  $\pi_i > 0$  for all  $i$

- Consider a process

$$x(t) = Ax(t - 1) \quad \text{for } t \geq 1$$

with an arbitrary  $x(0) \in \mathbb{R}^n$

- Then

$$\lim_{t \rightarrow \infty} x(t) = \lim_{t \rightarrow \infty} A^t x(0) = \pi \mathbf{1}' x(0) = (\mathbf{1}' x(0)) \pi$$

- Repeating this process with a different initial point,  $y(0)$  we obtain

$$y(t) = Ay(t - 1) \quad \text{for } t \geq 1$$

$$\lim_{t \rightarrow \infty} y(t) = (\mathbf{1}' y(0)) \pi$$

- Look at the coordinate-wise ratio

$$z_i(t) = \frac{x_i(t)}{y_i(t)}, \quad \lim_{t \rightarrow \infty} z_i(t) = \frac{(\mathbf{1}' x(0)) \pi_i}{(\mathbf{1}' y(0)) \pi_i} = \frac{\mathbf{1}' x(0)}{\mathbf{1}' y(0)}$$

- If we want

$$\lim_{t \rightarrow \infty} z_i(t) = \frac{1}{n} \mathbf{1}' x(0)$$

it can be done by choosing the initial values  $y_i(0) = 1$

## Push-Sum Algorithm for Consensus

We given a directed graph  $\mathbb{G}$

Every node  $i$  maintains scalar variable  $x_i(t)$  and  $y_i(t)$

These quantities will be updated by the nodes according to the rules,

$$x_i(t + 1) = \sum_{j \in N_i^{\text{in}} \cup \{i\}} \frac{x_j(t)}{d_j + 1},$$

$$y_i(t + 1) = \sum_{j \in N_i^{\text{in}} \cup \{i\}} \frac{y_j(t)}{d_j + 1},$$

$$z_i(t + 1) = \frac{x_i(t + 1)}{y_i(t + 1)}$$

- Each node  $i$  "knows" its out degree  $d_i$
- $N_i^{\text{in}}$  is the set of "in"-neighbors of node  $i$
- The method<sup>†</sup> is initiated with  $y_i(0) = 1$  for all  $i$ .

---

<sup>†</sup>D. Kempe, A. Dobra, and J. Gehrke "Gossip-based computation of aggregate information" In Proceedings of the 44th Annual IEEE Symposium on Foundations of Computer Science, pages 482491, Oct. 2003

F. Benezit, V. Blondel, P. Thiran, J. Tsitsiklis, and M. Vetterli "Weighted gossip: distributed averaging using non-doubly stochastic matrices" In Proceedings of the 2010 IEEE International Symposium on Information Theory, Jun. 2010.

## Perturbed Push-Sum: Scalar Case, Time-varying graphs

$$\begin{aligned}
 w_i(t+1) &= \sum_{j \in N_i^{\text{in}}(t) \cup \{i\}} \frac{x_j(t)}{d_j(t) + 1}, \\
 y_i(t+1) &= \sum_{j \in N_i^{\text{in}}(t) \cup \{i\}} \frac{y_j(t)}{d_j(t) + 1}, \\
 z_i(t+1) &= \frac{w_i(t+1)}{y_i(t+1)} \\
 x_i(t+1) &= w_i(t+1) + \epsilon_i(t+1)
 \end{aligned} \tag{1}$$

where  $\epsilon_i(t+1)$  are perturbations experienced by node  $i$

This allows for studying the (sub)gradient methods as a special perturbations

$$\epsilon_i(t+1) = \alpha_t \nabla f_i(z_i(t+1))$$

## Convergence Result

Consider the sequences  $\{z_i(t)\}$ ,  $i = 1, \dots, m$ , generated by the push-sum method.

**Lemma 1 (Key)** *Assuming that the graph sequence  $\{G(t)\}$  is  $B$ -uniformly strongly connected, for all  $t \geq 1$  we have*

$$\left| z_i(t+1) - \frac{\sum_{i=1}^m x_i(t)}{m} \right| \leq \frac{8}{\delta} \left( \lambda^t \|x(0)\|_1 + \sum_{s=1}^t \lambda^{t-s} \|\epsilon(s)\|_1 \right),$$

where  $\delta > 0$  and  $\lambda \in (0, 1)$  satisfy

$$\delta \geq \frac{1}{m^{mB}}, \quad \lambda \leq \left( 1 - \frac{1}{m^{mB}} \right)^{1/B}.$$

Define matrices  $A(t)$  by  $A_{ij}(t) = 1/(d_j(t) + 1)$  for  $j \in N_i^{\text{in}}(t) \cup \{i\}$  and 0 otherwise. If each of the matrices  $A(t)$  are doubly stochastic, then

$$\delta = 1, \quad \lambda \leq \left( 1 - \frac{1}{4m^3} \right)^{1/B}.$$

## Optimization

**The subgradient-push method can be used for minimizing  $F(z) = \sum_{i=1}^m f_i(z)$  over  $z \in \mathbb{R}^n$**

Every node  $i$  maintains vectors  $\mathbf{x}_i(t), \mathbf{w}_i(t)$  in  $\mathbb{R}^n$ , as well as an auxiliary scalar variable  $y_i(t)$ , initialized as  $y_i(0) = 1$  for all  $i$ . These quantities will be updated by the nodes according to the rules,

$$\begin{aligned} \mathbf{w}_i(t+1) &= \sum_{j \in N_i^{\text{in}}(t) \cup \{i\}} \frac{\mathbf{x}_j(t)}{d_j(t) + 1}, \\ y_i(t+1) &= \sum_{j \in N_i^{\text{in}}(t) \cup \{i\}} \frac{y_j(t)}{d_j(t) + 1}, \\ \mathbf{z}_i(t+1) &= \frac{\mathbf{w}_i(t+1)}{y_i(t+1)}, \\ \mathbf{x}_i(t+1) &= \mathbf{w}_i(t+1) - \alpha(t+1)\mathbf{g}_i(t+1), \end{aligned} \tag{2}$$

where  $\mathbf{g}_i(t+1)$  is a subgradient of the function  $f_i$  at  $\mathbf{z}_i(t+1)$ .

The method is initiated with arbitrary  $\mathbf{x}_i(0)$  and  $y_i(0) = 1$  for all  $i$ .

The stepsize  $\alpha(t + 1) > 0$  satisfies the following decay conditions

$$\sum_{t=1}^{\infty} \alpha(t) = \infty, \quad \sum_{t=1}^{\infty} \alpha^2(t) < \infty$$

Under this stepsize (and  $B$ -uniform strong connectivity), the algorithm produces the iterates that converge to a **consensual** minimizer of  $F(z) = \sum_{i=1}^m f_i(z)$  over  $z \in \mathbb{R}^n$ .

- Simple broadcast-based implementation: each node  $i$  broadcasts the quantities  $\mathbf{x}_i(t)/(d_i(t) + 1), y_i(t)/(d_i(t) + 1)$  to all of the nodes in its out-neighborhood\*\*, which simply sum all the messages they receive to obtain  $\mathbf{w}_i(t + 1)$  and  $y_i(t + 1)$ .
- The update equations for  $\mathbf{z}_i(t + 1), \mathbf{x}_i(t + 1)$  can then be executed without any further communications between nodes during step  $t$ .
- Convergence rate is of the order of  $O(\ln t/\sqrt{t})$  for convex functions and  $O(\ln t/t)$  for strongly convex functions<sup>#††</sup>
- Tatarenko and Touri 2015 (Non-Convex Distributed Optimization)

---

\*\*We note that we make use here of the assumption that node  $i$  knows its out-degree  $d_i(t)$ .

††<sup>#</sup>AN and Olshevsky *Distributed Optimization over Time-varying Directed Graphs* IEEE Transactions on Automatic Control 60 (3) 601-615, 2015

AN and Olshevsky *Stochastic Gradient-Push for Strongly Convex Functions on Time-Varying Directed Graphs* arxiv 2015

## Yet Another Issue

- The consensus-type algorithms discussed thus far will not produce convergent iterates when **a fixed stepsize** is used even when the functions  $f_i$  have Lipschitz gradients and  $\sum_{i=1}^m f_i(x)$  is strongly convex

- Brought to attention in work of Shi, Ling, Wu, and Yin (EXTRA) 2014, 2015

$$x_i(t+1) = \left( \sum_{j=1}^m a_{ij} x_j(t) \right) - \alpha_t \nabla f_i(x_i(t))$$

$$x^* = x^* - \alpha \nabla f_i(x^*) \implies \nabla f_i(x^*) = 0$$

- No hope that the algorithms using the diminishing step can achieve a geometric rate!
- They are still good - work well in noisy environment - just the stepsize cannot be constant
- Achieving linear rate - is it possible?

## Achieving Linear Rate: Static (Undirected) Graphs

$$\text{minimize } \sum_{i=1}^m f_i(x) \quad \text{subject to } x \in \mathbb{R}^n$$

Reformulate by making local copies

$$\text{minimize } \sum_{i=1}^m f_i(x_i) \quad \text{subject to } x_i = x_j \quad \forall i, j \in [m].$$

Exploit the fact that the agents are embedded in a connected graph

$$\text{minimize } \sum_{i=1}^m f_i(x_i) \quad \text{subject to } x_i = x_j \quad \forall i \in [m], \forall j \in N_i,$$

where  $N_i$  is the set of neighbors in the given graph.

It allows for solving it by using local agent communications by applying dual, or primal-dual approaches, which under suitable conditions admit linear rate ADMM, EXTRA, PG-EXTRA

- Ermin Wei (ADMM), Wei (Wilbur Shi), Wotao Yin (EXTRA, PG-EXTRA)

**Can linear rate be achieved in time-varying graphs?**

# Achieving Linear Rate: Time-varying (Undirected) Graphs

$$\text{minimize } \sum_{i=1}^m f_i(x_i) \quad \text{subject to } x_i = x_j \quad \forall i, j \in [m].$$

The agent system connectivity changes in time according to a graph sequence  $\{G_k\}$ .

$$\text{minimize } \sum_{i=1}^m f_i(x_i) \quad \text{subject to } x_i = x_j \quad \forall i \in [m], \forall j \in N_i(k),$$

where  $N_i(k)$  is the set of neighbors in the graph  $G_k$ .

**The constraint set  $\{x_i = x_j \quad \forall i, j \in [m]\}$  does not change, but the agents get a different “description of the set” every time they update.**

There is a hope for linear rate.

## Achieving Linear Rate: Methods that Track Gradients

- Centralized:  $z(t + 1) = z(t) + \alpha_t \sum_{i=1}^m \nabla f_i(z(t))$ .

- **Distributed Inexact Gradient Tracking (DIGing)**

Basic Idea: agents need to be "aware" that they are solving a "system problem", i.e., they should track the gradient sums of the other agents

For this, each agent uses a "surrogate" for the sum of gradients

$$x_i(t + 1) = \left( \sum_{j=1}^m a_{ij} x_j(t) \right) - \alpha_t \underbrace{g_i(t)}_{\text{est. of } \sum_{i=1}^m \nabla f_i(z(t))}$$

$$g_i(t + 1) = \left( \sum_{j=1}^m a_{ij} g_j(t) \right) + \nabla f_i(x_i(t + 1)) - \nabla f_i(x_i(t))$$

When the matrix  $A$  is doubly stochastic, it can be seen that

$$\sum_{i=1}^m g_i(t + 1) = \sum_{i=1}^m \nabla f_i(x_i(t + 1)).$$

- The convergence rate is geometric (variants for time-varying undirected and directed graphs)

## Algorithm NEXT (Lorenzo and Scutari)

Gradient-tracking approach to solve nonconvex problem  $\sum_{i=1}^m f_i(x)$

$$x_i(t+1) = \left( \sum_{j=1}^m a_{ij} x_j(t) \right) - \alpha_t \underbrace{g_i(t)}_{\text{est. of } \sum_{i=1}^m \nabla f_i(z(t))}$$

$$g_i(t+1) = \left( \sum_{j=1}^m a_{ij} g_j(t) \right) + \nabla \tilde{f}_i(x_i(t+1); t) - \nabla \tilde{f}_i(x_i(t); t-1)$$

where  $\tilde{f}(\cdot; t)$  is a *convex local approximation* of  $f$  at  $x(t)$  such that the linear approximations of  $f(x)$  and  $\tilde{f}(x; t)$  coincide at  $x = x(t)$ .

**NEXT is more general than DIGing**

**Our focus is on convex case - chasing a linear rate, while**

**Aldo's work is dealing with convergence properties for a larger class of functions**

## Compact notation

- Each node  $i$  has variable  $x_i \in \mathbb{R}^n$ , placed on the  $i$ th row of a matrix  $\mathbf{x}$ .

$$\mathbf{x} \triangleq \begin{pmatrix} - & x_1^T & - \\ - & x_2^T & - \\ & \vdots & \\ - & x_m^T & - \end{pmatrix} \in \mathbb{R}^{m \times n}.$$

- $\mathbf{x}$  is consensual if all rows are equal:  $x_i^T = x_j^T, \forall i \neq j$ .

$$\mathbf{f}(\mathbf{x}) \triangleq \sum_{i=1}^m f_i(x_i), \quad \nabla \mathbf{f}(\mathbf{x}) \triangleq \begin{pmatrix} - & (\nabla f_1(x_1))^T & - \\ - & (\nabla f_2(x_2))^T & - \\ & \vdots & \\ - & (\nabla f_m(x_m))^T & - \end{pmatrix} \in \mathbb{R}^{m \times n}.$$

- original problem  $\iff \min \mathbf{f}(\mathbf{x}), \text{ s.t. } x_i = x_j, \forall i \neq j$

## DIGing Method for Undirected Graphs

**DIGing: matrices  $\mathbf{W}(k)$  are doubly stochastic**

---

Choose step-size  $\alpha > 0$  and pick any  $\mathbf{x}(0) \in \mathbb{R}^{m \times n}$ ;  
 Initialize  $\mathbf{y}(0) = \nabla \mathbf{f}(\mathbf{x}(0))$ ;  
**for**  $k = 0, 1, \dots$  **do**  
      $\mathbf{x}(k + 1) = \mathbf{W}(k)\mathbf{x}(k) - \alpha\mathbf{y}(k)$ ;  
      $\mathbf{y}(k + 1) = \mathbf{W}(k)\mathbf{y}(k) + \nabla \mathbf{f}(\mathbf{x}(k + 1)) - \nabla \mathbf{f}(\mathbf{x}(k))$ ;  
**end**

---

Each agent  $i$ :

$$x_i(k + 1) = W_{ii}(k)x_i(k) + \sum_{j \in \mathcal{N}_i^{\text{in}}(k)} W_{ij}(k)x_j(k) - \alpha y_i(k);$$

$$y_i(k + 1) = W_{ii}(k)y_i(k) + \sum_{j \in \mathcal{N}_i^{\text{in}}(k)} W_{ij}(k)y_j(k) \\ + \nabla f_i(x_i(k + 1)) - \nabla f_i(x_i(k)).$$

$\mathbf{W}(k)$  is compatible with the graph  $\mathcal{G}(k)$ :  $W_{ij}(k) > 0$  when  $\{i, j\} \in \mathcal{E}_k$  and  $W_{ii}(k) > 0$ .

## Assumptions for Linear Convergence Rate for DIGing

- The functions  $f_i$  are convex with Lipschitz gradients (with Lipschitz constant  $L_i$ )
- The sum  $\frac{1}{m} \sum_{i=1}^m f_i$  is strongly convex with a coefficient  $\bar{\mu} > 0$
- The graphs  $\mathcal{G}(k)$  are  $B$ -connected: for some integer  $B \geq 1$ , the graph  $([m], \cup_{t=k}^{k+B-1} \mathcal{E}_t)$  is connected for all  $k$ .
- $\mathbf{W}(k)$  is doubly stochastic, compatible with the graph  $\mathcal{G}(k)$ , and there is a  $\tau > 0$  such that for all  $k$ ,

$$W_{ij}(k) \geq \tau \quad \text{whenever } W(k) > 0.$$

Under these assumptions we have the following result.

**Theorem 1 (DIGing: Explicit geometric rate)** *The sequence  $\{\mathbf{x}^k\}$  generated by DIGing converges to the unique optimal solution  $\mathbf{x}^*$  at a global  $R$ -linear rate  $O(\lambda^k)$ , where*

$$\lambda = \begin{cases} 2^B \sqrt{1 - \frac{\alpha \bar{\mu}}{1.5}}, & \text{if } \alpha \in \left( 0, \frac{1.5 \left( \sqrt{J_1^2 + (1-\delta^2)J_1 - \delta J_1} \right)^2}{\bar{\mu} J_1 (J_1 + 1)^2} \right], \\ B \sqrt{\sqrt{\frac{\alpha \bar{\mu} J_1}{1.5}} + \delta}, & \text{if } \alpha \in \left( \frac{1.5 \left( \sqrt{J_1^2 + (1-\delta^2)J_1 - \delta J_1} \right)^2}{\bar{\mu} J_1 (J_1 + 1)^2}, \frac{1.5(1-\delta)^2}{\bar{\mu} J_1} \right], \end{cases}$$

$$\delta \triangleq \max_{k \geq B-1} \left\{ \sigma_{\max} \left\{ \mathbf{W}_B(k) - \frac{1}{m} \mathbf{1}\mathbf{1}^T \right\} \right\} \text{ and } J_1 \triangleq 3\bar{\kappa} B^2 \left( 1 + 4\sqrt{m}\sqrt{\bar{\kappa}} \right),$$

for any step-size  $\alpha \in \left( 0, \frac{1.5(1-\delta)^2}{\bar{\mu} J_1} \right]$ , with  $\bar{\kappa} = \frac{L}{\bar{\mu}}$ ,  $L = \max_i L_i$ .

## Push-DIGing for Directed graphs

**Push-DIGing: matrices  $\mathbf{C}(k)$  are column stochastic**

---

Choose step-size  $\alpha > 0$  and pick any  $\mathbf{x}(0) = \mathbf{u}(0) \in \mathbb{R}^{m \times n}$ ;  
 Initialize  $\mathbf{y}(0) = \nabla \mathbf{f}(\mathbf{x}(0))$ ,  $\mathbf{v}(0) = \mathbf{1} \in \mathbb{R}^m$ , and  $\mathbf{V}(0) = \text{diag}\{\mathbf{v}(0)\}$ ;  
**for**  $k = 0, 1, \dots$  **do**  
      $\mathbf{u}(k + 1) = \mathbf{C}(k)(\mathbf{u}(k) - \alpha \mathbf{y}(k))$ ;  
      $\mathbf{v}(k + 1) = \mathbf{C}(k)\mathbf{v}(k)$ ;     $\mathbf{V}(k + 1) = \text{diag}\{\mathbf{v}(k + 1)\}$ ;  
      $\mathbf{x}(k + 1) = (\mathbf{V}(k + 1))^{-1}\mathbf{u}(k + 1)$ ;  
      $\mathbf{y}(k + 1) = \mathbf{C}(k)\mathbf{y}(k) + \nabla \mathbf{f}(\mathbf{x}(k + 1)) - \nabla \mathbf{f}(\mathbf{x}(k))$ ;  
**end**

---

$\mathbf{C}(k)$  is compatible with the directed graph  $\mathcal{G}(k)$ :  $C_{ij} = \frac{1}{1+d_j^o(k)}$  when  $(j, i) \in \mathcal{E}_k$  where  $d_j^o(k)$  is the out-degree of node  $j$  at time  $k$ .

## Specialized result

**Corollary 2 (DIGing: Polynomial networks scalability)** *If the graph is **undirected**,  $\mathbf{W}(k)$  is a lazy Metropolis matrix*

$$w_{ij}(k) = \begin{cases} 1 / (1 + \max\{d_i(k), d_j(k)\}), & \text{if } \{i, j\} \in \mathcal{E}_k, \\ 1 - \sum_{\ell \in \mathcal{N}(k)} W_{i\ell}(k), & \text{if } j = i, \\ 0, & \text{else,} \end{cases}$$

*and the agents choose the step-size*

$$\alpha = \frac{3(2/71)^2}{128B^2m^{4.5}L\sqrt{\bar{\kappa}}} - \frac{1.5}{\bar{\mu}} \left( \frac{(2/71)^2}{128B^2m^{4.5}\bar{\kappa}^{1.5}} \right)^2,$$

*then to reach  $\varepsilon$ -accuracy, the number of iterations needed by DIGing is*

$$O\left(B^3m^{4.5}\bar{\kappa}^{1.5} \ln \frac{1}{\varepsilon}\right).$$

(polynomial scaling in directed graph is still open)

## Numerical experiments: static directed graph

Each agent has a cost function given by a Huber loss. The DIGing is applied with a doubly stochastic matrix  $\mathbf{W}$  (off line construction); DIGing and DIGing-ATC are fast

## Numerical experiments: time-varying undirected graphs

Time-varying graphs are generated randomly from a static graph (arc activation chance 40%)  $\mathbf{W}(k)$  are Metropolis weights

## Numerical experiments: time-varying directed graphs

Time-varying graphs are generated randomly from a static graph (arc activation ratio 80% and then randomly choosing link direction)

## Distributed Resource Allocation

$$\begin{aligned}
 &\text{minimize} && f(\mathbf{x}) = \sum_{i=1}^m f_i(x_i) \\
 &\text{subject to} && \sum_{i=1}^m (x_i - r_i) = 0 \\
 &&& x_i \in \Omega_i, \quad \mathbf{x} = (x'_1, \dots, x'_m)'
 \end{aligned}$$

the functions are convex, and the sets are convex and closed. The agents are connected over an undirected graph  $G$ . By defining  $g_i(\cdot)$  as the indicator function of  $\Omega_i$ , i.e.,

$$g_i(x_i) = \begin{cases} 0 & \text{if } x_i \in \Omega_i \\ +\infty & \text{else} \end{cases}$$

we can cast the resource allocation problem as:

$$\begin{aligned}
 &\text{minimize} && h(\mathbf{x}) = \sum_{i=1}^m \underbrace{(f_i(x_i) + g_i(x_i))}_{h_i(x_i)} \\
 &\text{subject to} && \mathbf{1}'(\mathbf{x} - \mathbf{r}) = 0
 \end{aligned}$$

with  $\mathbf{x} = (x'_1, \dots, x'_m)'$ ,  $\mathbf{r} = (r'_1, \dots, r'_m)'$ , and  $\mathbf{1}$  is the vector with entries equal to 1.

## Connection to Distributed Optimization

Using the Lagrangian function for the resource allocation problem, we can write the optimality conditions as follows:  **$(\mathbf{x}^*, \mathbf{y}^*)$  is a primal-dual optimal pair for the resource problem iff**

$$\mathbf{1}'(\mathbf{x}^* - \mathbf{r}) = \mathbf{0}, \quad \mathbf{0} \in \partial h(\mathbf{x}^*) + \mathbf{1}(\mathbf{y}^*)'.$$

Letting  $L_G$  be the Laplacian of the underlying connectivity graph, and using  $L_G = U'U$ , the optimality conditions can be re-stated: given any scalar  $c \neq 0$   **$\mathbf{x}^*$  is a solution of the resource problem iff** there exists  $\mathbf{q}^*$  such that

$$\mathbf{x}^* - \mathbf{r} + cU'\mathbf{q}^* = \mathbf{0}, \quad U\tilde{\nabla}h(\mathbf{x}^*) = \mathbf{0}.$$

It turns out that these conditions are related to optimality conditions of distributed optimization problem

$$\text{minimize } h(\mathbf{x}) = \sum_{i=1}^m h_i(x_i) \quad \text{subject to } x_1 = \cdots = x_m.$$

**Table 1: Summary of optimality conditions**

Opt. Cond. of Resource Allocation	Opt. Cond. of Consensus Optimization
$\mathbf{x}^* - \mathbf{r} + cU'\mathbf{q}^* = \mathbf{0}$ $U\tilde{\nabla}h(\mathbf{x}^*) = \mathbf{0}$	$\tilde{\nabla}h(\mathbf{x}^*) + cU'\mathbf{q}^* = \mathbf{0}$ $U\mathbf{x}^* = \mathbf{0}$

Exploiting this connection, and using  $P$ -extra method<sup>‡‡</sup> the following algorithm is proposed

### Algorithm 1: Mirror-P-EXTRA

Each agent  $i$  chooses its own parameter  $\beta_i > 0$  and the same parameter  $c > 0$ ;

Each agent  $i$  initializes with  $x_i^0 \in \Omega_i$ ,  $s_i^0 = \tilde{\nabla}f_i(x_i^0)$ , and  $y_i^{-1} = \mathbf{0}$ ;

Each agent  $i$  **for**  $k = 0, 1, \dots$  **do**

$$y_i^k = y_i^{k-1} + \sum_{j \in N_i \cup \{i\}} \mathbf{L}_{ij} s_j^k;$$

$$x_i^{k+1} = \operatorname{argmin}_{x_i \in \Omega_i} \left\{ f_i(x_i) - \langle s_i^k, x_i \rangle + \frac{1}{2\beta_i} \|x_i - r_i + 2cy_i^k - cy_i^{k-1}\|_2^2 \right\};$$

$$s_i^{k+1} = s_i^k - \frac{1}{\beta_i} \left( x_i^{k+1} - r_i + 2cy_i^k - cy_i^{k-1} \right);$$

**end**

# Numerical Illustration

**Figure 1:** Plots of the normalized residual  $\frac{\|\mathbf{x}^k - \mathbf{x}^*\|_F}{\|\mathbf{x}^0 - \mathbf{x}^*\|_F}$  in a randomly generated connected graph of  $m = 100$  nodes.

## Conclusions

- We have algorithms with linear convergence rate even for time-varying (directed) graphs
- Theoretical bounds on the stepsize are "conservative" as the graphs are "general"
- Specializations to particular graph structure needed for practical purpose
- Large graphs - may require "partitioning" and coming up with speed ups in terms of better dependence on the size of the networks
